## ABSTRACT

The growing number of threats to the Earth's environment necessitates the gathering of fine-grained environmental sensor data to deepen our understanding of endangered species and assist in their protection. Traditional techniques for gathering environmental data, such as periodic field studies or satellite imaging, do not produce adequately detailed or persistent information. Self-organizing wireless networking provides an ideal way to quickly deploy and gather data from sensor networks in the field. The design of a practical, low-cost, and self-organizing wireless sensor network, TephraNet, is examined. This thesis also explores an implementation and deployment of TephraNet in Hawaii Volcanoes National Park to learn about the endangered ground plant *Silene hawaiiensis*.

Thesis Supervisor: Michael J. Hawley  
Title: Assistant Professor of Media Arts and Sciences

## Acknowledgements

No project as large and ambitious as the design and deployment of TephraNet would be possible without the support of many people. The author would like to extend a special thanks to the following people and organizations.

**Prof. Michael Hawley** for encouraging me to do things and go places I wouldn't have even imagined a few years ago and for building such a diverse and talented group of people to work with in PIA. Also thanks for the many great pictures of this project that appear in this thesis.

**Prof. Kim Bridges and the rest of University of Hawaii PODS Team** for providing a real application for TephraNet, and for their limitless patience with its multiple revisions and field test failures.

**Dr. Robert Poor**, for taking a leap of faith in me when I was an undergraduate sophomore with the Everest Project, getting me interested in this whole wireless self-organizing thing, and for all his work, support, and guidance through this project.

**Roshan Baliga, Ben Brown, Paul Pham**, my amazing UROPs, who dedicated crazy amounts of time to this, and made it possible- porting operating systems, hacking assembly code, and doing lots of hardware design and debugging, even while the Waikiki Beach was calling.

**Chris Newell**, for providing a superhuman amount of administrative support and encouragement and generally making everything happen- and going way beyond the call of duty to assist in any way.

**Paul Covell**, for taking time out of his job and life to help out on this project, and for coming out to Hawaii and keeping me sane.

**Matt Reynolds** for putting up with my many RF questions, all the design advice he gave, and the generous use of his RF test gear.

**Charlotte Burgess Auburn** for her encouragement throughout this project, and all her many hours of assistance in editing this thesis.

The generous support of **Dr. Sri Kumar and the SensIT program at DARPA**, who provided much of the funding for this project and provided a collaborative environment in which this joint University of Hawaii/MIT Media Lab project could occur.

The **National Park Service and US Geological Survey Hawaiian Volcano Observatory** for their interest in this project and for providing the wonderful facilities, internet connections, and study site that we used while in the field.

**My parents, Dr. James and Prof. Erlinda Wheeler**, for all their support throughout my life, putting education first, and for always encouraging me to do my best at anything I did.

# Chapter 1 Overview

## 1.1 Introduction

Researchers at the University of Hawaii Botany Department would love to understand the ecology of the rare *Silene hawaiiensis* plant. Existing only in a tiny microclimate region at the edge of a volcano crater in Hawaii Volcanoes National Park, little is known about this plant or its habitat. In an age of satellites and weather stations everywhere, it is hard to believe that so little could be known about the climate this plant lives in. The details of its habitat are too small to be noticed by satellites. The nearest weather station, a mere 3.5 miles away, is in a rainforest, while the *Silene* plant appears to be growing in a desert.

*Little is known about the hardy Silene plant. It is found only in one microclimate zone on the Big Island of Hawaii.*

Photo by Kim Bridges

**Figure 1.1 *Silene hawaiiensis* in Hawaii**

The lack of knowledge about the *Silene* plant and its habitat is just one example of a much broader problem. The environment of the earth is under siege. Pollution from industrial processes are reaching even the most remote points of the earth and affecting the complex ecosystem in ways that are barely understood. We have no time lapse view of the earth's environment. Tools that can capture a fine grained picture must be developed — and must be self-maintaining if there is to be any hope of blanketing the earth with them. The TephraNet system provides one

example of a tool that can be used to assist in gathering long term sensory data. This thesis describes the TephraNet system in detail and overviews the deployment in the *Silene*'s native environment.

*TephraNet weather station disguised as a rock (center), silently gathers data about the Silene's environment.*

Photo by Michael Hawley

**Figure 1.2 TephraNet Weather Rock**

The TephraNet system described in this thesis consists of around 100 miniature weather stations designed to capture ecodata and relay it back for analysis. Due to the terrain covered by the *Silene* habitat, and the need for a fast deployment, the system was wireless and self-organizing. The system, disguised as rocks and tree branches was sprinkled around the *Silene* habitat. Each weather rock or branch is both a data gathering device and a relay point for other weather stations. The system organizes itself into a network and passes the data back to collection point.

## **1.2 Motivation**

In addition to the desire to create an environmental monitoring system to aid in the study of endangered species, this thesis is motivated by several additional goals.

### **1.2.1 Platform for the study of Self-Organizing Wireless Networks**

The relatively young field of self-organizing wireless networks has focused much of its effort on the use of simulators, such as NS-2 [NS01], for development and testing of algorithms. While simulators are valuable for getting a rough idea of how a particular algorithm performs, the current simulator technology either requires vast resources to be accurate, or does

*TephraNet aims to provide a reference platform for environmental sensing and self-organizing network research.*

not capture many of the details of a real-world, resource constrained environment [Heidemann00].

Since simulators alone are not adequate for detailed testing of self-organizing wireless networks, a standard physical platform is needed to complete the testing suite used. The few testing platforms that have been built to date are primarily high cost and therefore prohibitive for research on large networks [Cerpa01] [Rockwell01]. This suggests the need for a low-cost, readily manufactured platform to serve as a standard testing environment for self-organizing wireless networks.

### **1.2.2 Proof of concept for self-organizing wireless networks applied to environmental sensing**

An additional goal of this thesis is to demonstrate the viability of self-organizing wireless networks as a tool for use in environmental sensing. Current approaches, which are detailed below in Chapter 2, often yield only a brief snapshot of an area, or a high level view that misses out on important micro-climate details. Self-organizing wireless networks offer one possible approach towards filling in the gap in the current set of tools. The wireless and self-organizing network approach to these tools offers potential advantages in setup and maintenance costs over traditional wired approaches. Through the field deployment of a TephraNet system, this thesis aims to show the usefulness of this technology as an environmental research tool.

### **1.2.3 Validation of GRAd Routing Algorithm**

The development of the TephraNet system was inspired in part by previous work in the Personal Information Architecture group at the MIT Media Laboratory on Hyphos and GRAd, by Dr. Robert Poor [Poor01]. The routing algorithms proposed by that research received preliminary testing in a real-world system, ArborNet, but were not fully implemented for that revision. One motivation for this thesis is the testing of a complete implementation of the GRAd routing algorithm in a physical installation.

*ArborNet was the precursor to TephraNet and provided many useful design lessons.*

**Figure 1.3 ArborNet**

#### **1.2.4 Scope**

The scope of this thesis includes the goals stated in this section, primarily focusing on the design of the TephraNet system. This thesis does not focus on the analysis or interpretation of environmental data, but rather on the system to gather that data.

### **1.3 Thesis Structure**

The remainder of this thesis is comprised of four chapters. Chapter 2 provides a short background on traditional environmental sensing as well as a review of prior work in self-organizing wireless networks.

The design goals and high level design of the TephraNet system are presented in Chapter 3. The section begins with the design requirements and constraints, and follows with a view of the hardware and software systems that comprise TephraNet.

A prime motivation for this work is a field-deployment of the platform to test out the design in a non-laboratory environment. Chapter 4 contains a description of the field-deployment in Hawaii Volcanoes National Park. Beginning with the design of deployment-specific portions of the system, the section concludes with details about the study site and the field test.

The test of the system in Hawaii uncovered interesting findings relating to the networking algorithms used in the system design. Chapter 5 discusses these results, how well the system attained its goals, and future directions for work in this area.

## Chapter 2 Background Research and Context

### 2.1 Existing Environmental Sensing Technologies

A review of the existing methods used for the collection of environmental data for scientific research reveals a gap in the selection of tools that motivated the design of the TephraNet system.

Existing methods for gathering environmental data about a study area fall primarily into two categories. The first is what could be termed traditional field measurement techniques, including scientists in the field, and individual sensor devices, such as weather stations. The second primary category is satellite imagery.

*Traditional field research involves manual gathering of information in the field.*

Photo by Michael Hawley

**Figure 2.1 Gathering Data in the Field**

Traditional field measurement techniques rely on researchers in the field using hand-held and portable instrumentation to gather data about a specific site. This works well for isolated or small regions, and for measurements that do not need to be taken with frequency. However, once a measurement is required with a frequency greater than weeks or days, scientists usually turn to automated equipment, such as remote weather probes.

*Remote weather probes, such as this one at Everest Base camp, capture a pinpoint view of the weather at a place.*

*Photo by Matthew Lau*

**Figure 2.2 Everest Weather Probe**

Remote weather probes, such as the Everest Weather Probe, developed at the MIT Media Lab, can autonomously measure weather conditions every hour and report them via a satellite connection [Lau98]. These measurements give a clear picture of the weather at a particular point on Everest, but fail to show what the weather is like on the whole mountain. Both hand measurement and remote instrumentation often lack the ability to provide the detailed view of what is going on. For example, on the Big Island of Hawaii, many micro-climate zones exist. A weather station located in a rainforest may not be able to provide any information about the desert immediately next to it.

*Satellite images provide great big-pictures views, but often miss important details.*

**Figure 2.3 Satellite Weather Map**

Satellite imaging provides the ultimate big-picture view of an environment, often able to take in a whole continent or hemisphere at a time. This overview image is useful for capturing geographically large trends, such as the movements of a large storm. What satellite imagery is often lacking is the fine grained detail that can capture the most important events or trends in a small environment. A botanist wishing to learn about the pollination mechanisms for a particular flower may wish to know the wind characteristics right next to the plant- a level of detail beyond what a weather satellite captures.

A new type of observation tool is required that can measure and record detailed and long term information about an environment in a cost effective manner. Consider the scenario where an animal researcher wishes to learn what sort of sounds a particular animal makes when a very rare event occurs. Traditional observation techniques such as a few hidden microphones or a researcher in the field may take an unacceptable amount of time or money to record the sound. If the habitat of the animal could be blanketed with miniature sound recorders in a cost effective manner, then the answer could be heard sooner.

## 2.2 *Self-Organizing Wireless Network Research*

*Self-organizing wireless network research presents an ideal match for many of the needs of the environmental sensing community.*

One field of research in the networking and defense communities has great potential for application to the environmental sensing problem. Self-organizing (or ad-hoc) wireless sensor networking is an area that until recently existed almost entirely in simulation. The research in this field centers on the development of routing algorithms that allow a random collection of wireless nodes to form a data network. Each node in the network is not only a potential sensor or data source, but also a relay node. The network is like a bucket brigade, where messages are passed along from neighbor to neighbor on the way to the final destination.

These networks offer many advantages over traditional wireless networking, including spatial frequency reuse, increased reliability, and low setup and maintenance overhead. [Poor01] presents a good overview of the advantages of this type of networking. An overview of the types of routing algorithms present in the research field can be found in [Broch98] and [Johansson99]. Readers interested in a comparison of the GRAd

routing algorithm used in the TephraNet implementation and other more mainstream algorithms, such as AODV and DSR, should refer to [Wheeler00].

*The ad-hoc networking research community needs a hardware platform to compliment the currently used software simulators.*

To date, most of the research in the field has been performed in simulators, most notably in NS-2 (network simulator 2) [NS01]. While network simulation provides a reasonable first pass at simulating the characteristics of an algorithm, it does not capture many real world characteristics of wireless networks. In particular, the NS-2 simulator does not provide a particularly accurate wireless simulation environment. It is missing key elements such as simulation of external interference and changing noise floors. An evaluation of the make up a self-organizing sensor network beyond the routing algorithms is difficult to do without a physical platform. A few university and military research groups, notably [Cerpa01] and [Rockwell01] have created physical platforms for ad-hoc networking research. These platforms have not been scaled to large numbers, primarily because of prohibitive cost, and are not common between the various groups, making result comparison difficult. A low cost sensor platform, COTS SmartDust, suitable for field deployment is presented in [Hollar01]. Although this platform is low cost and has been released to the community, it has very limited computing and memory resources, and runs a custom operating system, making it unlikely to be a good general purpose research platform.

*Current platforms for sensor network study tend to either be prohibitively expensive or very resource constrained.*

*Photo from Seth Hollar*

**Figure 2.4 COTS SmartDust Platform**

The TephraNet platform, described in detail in the next chapter, provides a solution for both environmental sensing and self-organizing wireless

network research. It provides environmental researchers with a prototype sensing platform, while also providing ad-hoc networking researchers a common physical platform on which to test out algorithms.

## Chapter 3 TephraNet System Design

### 3.1 Functional Description

The TephraNet platform consists of a number of the basic building blocks – TephraNodes. These nodes may be used both as a sensor network to gather environmental data, as discussed in the previous sections, or as the basic components of a network algorithm test bed.

*TephraNodes  
awaiting  
programming and  
deployment.*

*Photo by Michael Hawley*

**Figure 3.1 TephraNodes**

#### 3.1.1 TephraNet as Sensor Network Demonstration

In the context of the TephraNet platform as a platform for environmental sensor data gathering, each TephraNet consists of two basic pieces: TephraNodes with sensors, and gateway nodes to collect data. In order to construct a complete data gathering solution, a number of TephraNodes are placed around a target observation area. The nodes, using the service discovery and network routing services, form an ad-hoc network as described in Chapter 2. Once formed, each node in the network can both relay packets for their neighbors, as well as gather sensor data. The TephraNodes can perform local processing on the data before determining to send reports to the data collection points within the network.

### 3.1.2 TephraNet as Networking Algorithm Testbed

In order to ensure that the TephraNet platform can also be used as a general network routing algorithm test bed, the software pertaining to the networking routing must be replaceable with another network routing algorithm. The hardware and software that makes up TephraNet must contain enough expansion abilities to be amenable to hosting both software and hardware peripherals that would be desired for the testing of other network routing algorithms.

## 3.2 Design Goals

*TephraNet is designed  
with  
manufacturability,  
low power and ease  
of use in mind.*

TephraNet has several design goals that are presented in this section. These goals derive from the thesis goals of creating TephraNet as a platform for both environmental field work and for testing wireless networking algorithms.

### 3.2.1 Manufacturability

The goal of using the TephraNet platform as a common hardware system to test networking algorithms dictates that the components used in the design are easily procurable in research lab quantities and ideally manufacturable and serviceable in a standard academic laboratory environment. Since the TephraNet system was to be field deployed during the course of the thesis research, the designed platform had to be manufacturable within a short time schedule. This required using off-the-shelf and readily available components where possible and ensuring that the system could be tested easily.

### 3.2.2 Low Power

In order for the TephraNet system to be useful for most field research, the system has to function for at least a month on available power. This requirement dictates that all the hardware designed into the platform is as generally low power as possible and have special low-power or sleep modes where possible. A software power management system is required in addition to the hardware both of which will effectively control the low power modes of the hardware in order to extract maximum battery life.

### **3.2.3 Ease of Development and Software Flexibility**

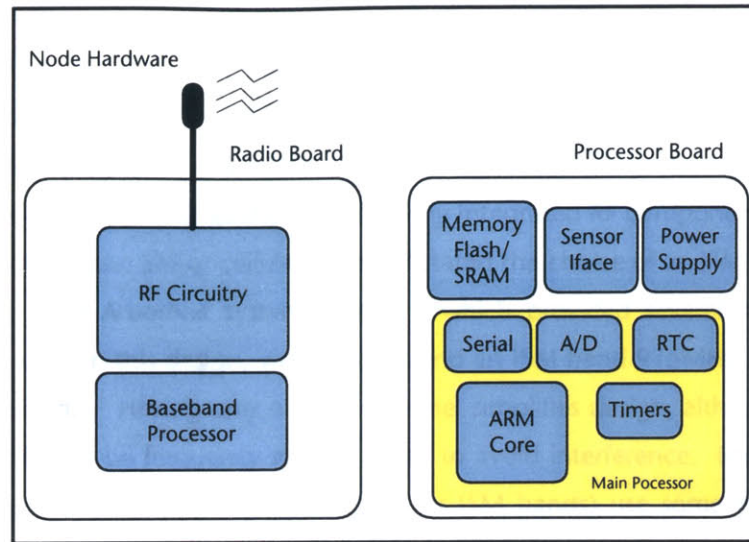

A major goal of the TephraNet platform is ease of development, both for hardware components and software components. Due to the short development and manufacturing schedules, the amount of custom component design required (i.e. custom chips, custom software) should be minimized. Design environments for the hardware and software are important beyond the development of the initial platform. Developing additional software and hardware components for the finished system should be easy. Those who wish to use TephraNet as an environmental platform should have to do minimal work to add sensors and configure reporting characteristics, while those who use TephraNet as a test platform should have a well designed and open software environment in which to test their algorithms.

### **3.2.4 Autonomous**

The TephraNet system needs to be autonomous and easy to use in order to cater to people not familiar with the field of networking. Beyond the ability of the system to route data without configuration, this includes the setup and on-going maintenance of the network. As new nodes are placed into the network during initial deployment and any future expansions, they should integrate with a minimum of effort. The network should also be able to automatically adjust to new services and data collection points placed into the network.

## ***3.3 Hardware Platform Description***

This section presents a high level view of the hardware, showing block diagrams of the system and noting rationale for specific hardware component choices. Readers interested in obtaining detailed schematics and parts listings should refer to Appendix A: Hardware Design.

**Figure 3.2 TephraNode Hardware**

Each of the basic hardware blocks is shown in Figure 3.2. Early in the design process, the blocks comprising the radio were placed on a second board. This separation eased the simultaneous development of the analog RF board and the digital processor board. The size of the two boards is the same in order to facilitate an easy mechanical interconnect. The size is the minimal optimal size to act as a good groundplane for a  $\frac{1}{4}$  wave commercially available “whip” antenna for the radio. The completed board stack can be seen in Figure 3.3. The specific motivation behind the choice of each component is presented below. The overall motivation is for a low-cost flexible platform.

*TephraNode hardware: the radio is on top, the processor on bottom.*

*Photo by Michael Hawley*

**Figure 3.3 TephraNode Hardware**

### 3.3.1 Radio

*The radio was selected to operate in a license free band and be frequency agile.*

Several factors motivated the choice of radio for this design. First is the need to operate in an unlicensed band (also known as an ISM band- Industrial, Scientific, and Medical). The regulatory issues surrounding licensed bands, as well as the lack of tightly integrated RF components for bands other than SM or cellular bands, dictated the choice of an ISM band system. The ArborNet system [Poor01], which provided several design lessons used in this design, was build around an ISM band 915MHz single channel radio. Having only a single channel simplifies design, although it is desirable to be frequency agile in order to avoid interference. Most RF systems operating in unlicensed bands (or ISM bands) use some spread spectrum technique in order to comply with FCC Part 15 regulations. The ability to use a spread spectrum technique was therefore also a consideration in the design of the radio. Also, since some networking algorithms make use of received signal strength indicator (RSSI) to determine link quality and also adjust output power, an RSSI output and adjustable transmit power are required. Some commercial RF systems, such as 802.11 meet these requirements, although their power consumption is too high for use in the TephraNet system given the lifetime required.

The radio module is designed around the Texas Instruments TRF6900 ISM band transceiver. This IC contains much of the circuitry required to produce a radio module, which simplifies design and minimizes size. It also has substantially lower power consumption than other available radio IC's, as well as all of the features required above. The radio module is designed to operate at a raw channel data rate of 100kbps in the 902-936MHz band. Transmit power is controllable between approximately -20dBm and +4.5dBm. The radio module is attached to a ¼ wave whip antenna manufactured by Lynx Technologies, selected for its good performance, reasonable size, and low cost. The module has a measured range of approximately 150-300ft in open space.

One unusual feature in the radio design is its low cost crystal reference. Traditionally, highly accurate, expensive frequency references are required for RF systems. Since this radio is frequency agile, the software compensates for any inaccuracy in the crystal by adjusting the PLL in the

radio based on a stored measurement of the crystal frequency from testing. Mechanisms are in place to allow software compensation of frequency drift due to temperature fluctuations as well. Readers interested in the details of the design of the radio modules can refer to Appendix A.

### **3.3.2 Radio Baseband Processor**

The baseband processor controls the radio module. It configures the radio, controls the power, transmit/receive state, formats the data correctly for transmission, as well as decodes received data. While it is common for a baseband processor to be implemented as a custom piece of hardware (as in 802.11 or Bluetooth RF systems), the design cycle for such a device was beyond the available time for the design. Because of the relatively low data rates involved, the TephraNet design uses a microcontroller processor to implement the baseband. Using a microcontroller also allows the baseband to be changed by future users of TephraNet.

Several low-power and low-cost microcontrollers were evaluated, including the PIC series from Microchip, and the AVR series from Atmel. The most important factor in the choice was the amount of available memory. Previous designs such as ArborNet encountered development difficulty due to lack of RAM space within the microcontroller to act as buffer space for incoming and outgoing packets. The Atmel AT90S8535 was chosen due to its large amount of RAM (512 bytes). The Atmel chip also contains an A/D converter, which is used to sample the analog RSSI output of the radio, a counter which can be used as a real time clock, and low power modes that allow power to be minimized. The implementation of the baseband features using the Atmel chip is discussed below in Section 3.4.2.

### **3.3.3 Main Microprocessor**

*The main processor is an ARM7TDMI, offering the best MIPS/watt ratio available today.*

The processor chosen for the main system microprocessor is the Samsung S3C3410X, which is based on an Advanced RISC Machines ARM7TDMI 32bit processor core. The ARM7TDMI core was selected early in the design process as the main core for several reasons. First, the ARM7TDMI core is one of the most power efficient 32bit core in common use. Its widespread use in industry ensured that it had a significant amount of

development tool support. Although a 32bit chip seems like potential overkill for this application, it ensures that time is not wasted attempting to squeeze code into a resource constrained part.

The Samsung chip was chosen out of the many chips designed around the ARM7TDMI core for its high level of integration and availability. Targeted at MP3 players and handheld devices, this chip integrates many essential peripherals, such as serial ports, memory controllers, a real time clock, and a high resolution (10 bit), high speed (500K samples/sec) A/D converter. The chip also contains several useful reduced power modes, including sleep and reduced speed. The high level of integration also ensures a more power efficient design than using separate chips to implement each function [Samsung01].

#### **3.3.4 Memory**

The TephraNet design ensures that there is a reasonable amount of memory to work with for the same reasons that a 32bit processor was chosen. Both program space as well as data space are maximized to avoid wasting development effort on minimizing resource use and to allow debug status to be maintained. Flash memory was selected as the memory technology for the program space since it can be programmed by the processor without the high voltage requirements of standard EEPROM and does not have the current draw or mechanical parts a hard drive would. SRAM is the choice for system memory technology because of its static nature. No power is used to refresh the memory, and SRAM can retain data even while the system is asleep.

The original design specified the use of an Intel stacked chip SRAM and flash component that combined 256KB SRAM and 2MB flash components into a single chip. However, subsequent availability problems led to the selection of separate 512KB Toshiba SRAM and a 4MB Intel flash chips. Unfortunately, availability also dictated the choice of a uBGA packaged for the Intel flash chips, which proved to be a large hurdle in manufacturing. Many smaller manufacturers and most academic labs are not set up for this miniature package, and future revisions should select a more standard package.

### 3.3.5 Expansion I/O

The TephraNode processor board contains over 100 pins of I/O, listed in Table 3.1.

Serial Port	4 pins	Standard RS232 port, primarily for debugging
JTAG Connector	20 pins	Used for programming and debugging the processor
Radio Interface	18 pins	Synchronous serial data and radio control signals
Analog Sensor Port	20 pins	Provided access to 5 A/D ports
Memory Bus Connector	60 pins	Access to memory and data bus of processor

**Table 3.1 TephraNode I/O**

The analog sensor port connects internally to an array of resistor pads that can be configured to attach to a large family of analog sensors without additional external hardware (all resistive or voltage out sensors). The memory bus connector allows more complicated modules to be added onto the TephraNode that provide additional services or features not in the base system. For example, a digital camera or high speed radio (such as 802.11) could make use of this port. All of the I/O ports mentioned are discussed in further detail in Appendix A.

### 3.3.6 Power Supply

A power supply was placed on the TephraNode to reduce the number of boards, although this could potentially reduce the flexibility of the system by forcing the user to use only certain battery configurations. The power supply can be bypassed to minimize this problem. The power supply is based on the Maxim MAX639 switching power supply controller IC. This controller was selected primarily for its very low ( $\sim 10\mu\text{A}$ ) quiescent current (current drawn when no load is present) and high efficiency ( $>90\%$ ) [Maxim97]. The low quiescent current simplifies the design significantly by allowing the power supply to stand alone without a special sleep control signal from the processor. A low dropout voltage and high efficiency ensure maximum utilization of the power stored in the power source.

### 3.4 Software Overview

The software running on the TephraNet system provides numerous services related to forming and maintaining a network, sending and receiving data, and managing power consumption at nodes. A diagram showing the various software components present in TephraNet is shown in Figure 3.4. This section presents a functional view of the software in the TephraNet system. Implementation details are located in Appendix B: Source Code Listing.

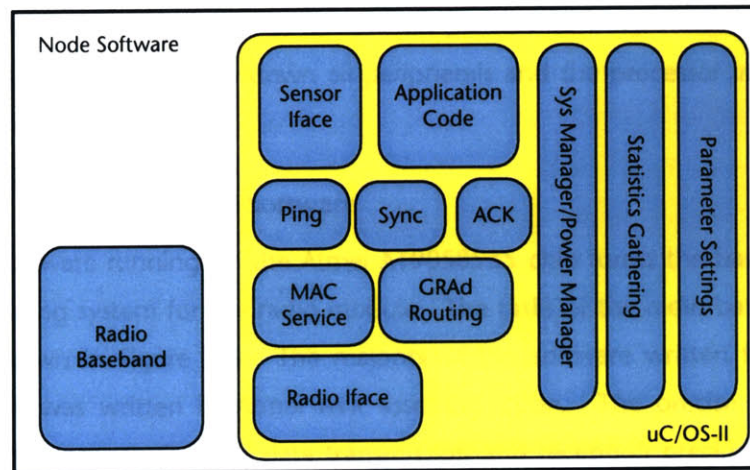

Figure 3.4 TephraNode Software

#### 3.4.1 Node Lifecycle

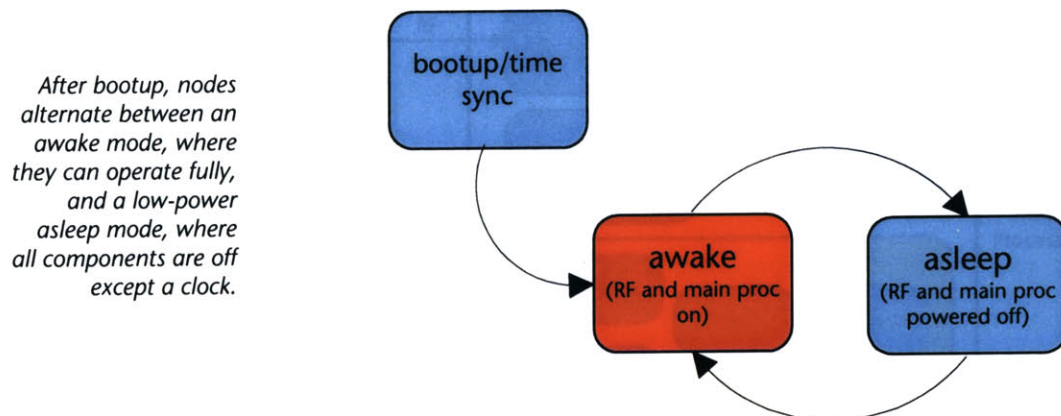

Figure 3.5 Node Lifecycle

A TephraNode progresses through several states during its lifecycle. When a node starts up, it goes through a bootup phase. During this period of

time, the operating system is booted, and hardware peripherals are configured. The node then enters a synchronization period, where it attempts to synchronize its network time with any neighbor nodes that may be present. Once synchronization has been obtained, the node enters normal operation. During this period of time, the node alternates between being awake, and being asleep. All nodes in a TephraNet follow the same waking and sleeping schedule due to their synchronization. While awake, a node can run application level software which can generate and receive packets from the network, or it can simply act as a repeater. The node can also forward on packets for other nodes. While asleep, the node powers down all peripherals and the processor in order to conserve power.

### 3.4.2 Radio Baseband Software

The software running on the Atmel AT90S8535 chip forms the baseband processing system for the radio module. The tasks of the radio baseband are shown in Figure 3.6. The majority of the software written for this section was written in Atmel AVR assembly code. The precise timing requirements required for data transmission and reception precluded the use of a higher-level language. A partial listing of source code can be found in Appendix B.

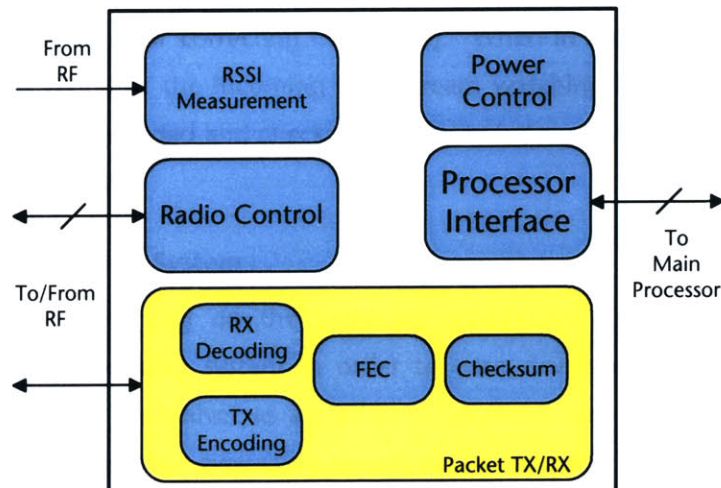

Figure 3.6 Baseband Functions

#### **3.4.2.1 Power Control**

The baseband software provides power down control of the RF section of the circuit as well as the baseband processor. When instructed to do so by the main processor, the baseband software can power down the RF section of the circuit and then suspend its own operation. Operation continues upon reception of the proper signal from the main processor.

#### **3.4.2.2 Processor Interface**

The baseband software controls the interface to the main system processor. This interface consists of signals that allow each processor to send an interrupt signal to the other. Packet and configuration data is exchanged over a synchronous serial port. The interface to the main processor is detailed further in Section 3.4.4.3 as well as Appendix A.

#### **3.4.2.3 Packet Transmission and Reception**

The primary job of the baseband processor is to provide the mechanism by which packets are exchanged “over the air”. During transmission, the baseband processor takes a packet from the main processor, prepends the RF level header (composed of a synchronization sequence and start symbol), and sends the data in a DC balanced format. The final version of the code utilized Manchester encoding, which uses 2 bits per symbol to ensure a DC balance [Rappaport96]. The transmission also includes a simple forward error correcting code (FEC). When in receive mode, the processor monitors the incoming data stream watching for valid packet data, which is decoded and checked for validity before transmission to the system processor.

#### **3.4.3 Operating System**

The software running on the Samsung ARM7TDMI (main) processor requires an operating system in order to ease development for those wishing to use TephraNet as a platform. uC/OS-II was selected as the operating system after evaluating several commercial and free embedded operating systems. uC/OS-II is open source, well documented, and provides all the services that are required for development. Other operating systems evaluated required licensing fees that are prohibitive for most academic environments. Many others contain features considered

unnecessary, increasing the code size with no benefit, and were not as well documented as uC/OS-II. Additionally, this OS had previously been ported to a close relative of the Samsung chip used as the main processor in TephraNet, easing the job of porting the operating system to the TephraNode hardware. Details about uC/OS-II can be found in [Labrosse99].

### 3.4.4 Packet Transmission and Reception

#### 3.4.4.1 Packet Types

During normal waking operation, the node constantly waits for incoming packets. When a packet is received, it is examined to discover what types of data are contained within. Packet types are shown in Table 3.2. Multiple segments of different types can be contained within a single “over the air” packet. Each segment is sent off to the corresponding “handler” for that type. For example, all packets that contain a GRAd routing header are handed over to the GRAd service (described below) for routing. Many of the packet types here are related to services described in subsequent sections.

Packet Type	Description
SYNC	Contains current time of sender
GRAD	GRAd routing header type
DISCO	GRAd route discovery packet
PING	Ping packet
PONG	Reply to a ping packet
ARQ	Request the whole packet be acknowledged
ACK	Packet acknowledgement
NEIGHBOR_REQUEST	Request a node to discover all its neighbors
NEIGHBOR_REPORT	Report of who the senders 1 hop neighbors are
LINK_REQUEST	Request a link state report from a node
LINK_REPORT	Report of the senders link strength to a neighbor
PARAM_SET	Sets the parameters in a node
PARAM_REQUEST	Requests the current node parameters
PARAM_REPORT	Report of the current parameters
STATS_RESET	Resets all statistics to startup values
STATS_REQUEST	Requests a statistics report from a node
STATS_REPORT	Report of the current statistics values in a node
APPX_REPORT	Sensor value report
COST_TABLE	The GRAd routing table of the sender
BOOT_REPORT	Contains information about a nodes bootup
ENTER_TEST	Causes a node to enter a “sleepless” mode
EXIT_TEST	Exits the test mode above
START_ASYNC	Tells a node to wait for a specific node to wake

	up or come on-line and then to run a link strength test
STOP_ASYNC	Stops the above process

**Table 3.2 Packet Segment Types**

#### **3.4.4.2 MAC Service**

The MAC (Medium Access Control) service provides access control for the radio. This service regulates when packets are sent out over the radio interface. TephraNet implements an 802.11 style MAC layer, described in [IEEE99]. Since all packets sent are broadcast, the entire RTS/CTS system is not implemented. The MAC service implements only the broadcast portion of the 802.11 MAC specification. This service can be modified or replaced to examine the effect the MAC algorithm has on various routing algorithms.

#### **3.4.4.3 Radio Interface**

*DMA allows packet transfers to occur in the background without processor attention.*

The radio interface is the portion of the TephraNet code that communicates with the radio. A DMA-based (Direct Memory Access) interface to the radio baseband was developed to ease the main processor overhead of processing incoming or outgoing packets. Normally, the radio module code sits idle, waiting for the radio baseband to indicate that a packet has been received. When the baseband receives a valid packet, it transfers the data via a synchronous serial port directly into the main processor memory space (using the DMA controller on the Samsung processor). The processor is then interrupted, and the radio module comes to the foreground to parse the packet. The parsed packet is then handed up to the routing service and the application software for processing.

When a software module is ready to transmit, it calls an access function in the radio module that sets up the transmission. First the radio baseband is interrupted to indicate the beginning of transmission. The radio baseband then uses the DMA interface to read the packet to send directly out of the processor memory without further main processor intervention. The packet is then sent by the baseband as described in Section 3.4.2.3.

### 3.4.5 GRAd Routing Service

TephraNet implemented the GRAd routing algorithm for this revision. In order to use TephraNet as a general network algorithm testbed, the GRAd algorithm can be replaced with another algorithm, such as AODV (Ad-hoc On-demand Distance Vector) or DSR (Dynamic Source Routing). All of the main GRAd feature set was implemented for this revision as described in [Poor01]. This implementation parameterized several GRAd settings. These are shown along with other parameterized system settings below in Table 3.3. These parameters can be adjusted during the course of network operation.

### 3.4.6 Synchronization Service and Power Management

*The synchronization service is used to power manage the network by sleeping all nodes simultaneously.*

The synchronization service (SYNC) is responsible for ensuring that the time at each node in the network is uniform. This plays a central role in power management. The largest source of power consumption in a low power network is the power used for reception [Wheeler00]. Although high power radios consume far more power during transmission than reception (due to the power amplifier), current low transmit power radios consume the same or more power during receive than transmit. A major goal for minimizing power consumption is reducing the amount of time the receiver is on. In traditional base-station architectures where a single high power base station can communicate with all nodes (such as in a cellular network), the receiver at each node can be controlled by the base station, who schedules all network traffic. In an ad-hoc network, one approach to distributed synchronization, with the goal of being able to turn off radio receivers, is presented in [Xu00].

The basic description of the synchronization system is that a packet describing a node's current time is sent out periodically. Every node receiving this packet averages their internal time with the time heard. In this way, the time across all the nodes in the network converges to a common time. This system is based on the distributed synchronization system proposed by Poor in [Poor01].

This basic concept was implemented in the TephraNet system, with some modifications. The first is a bootup phase. During this period of time, they do not send any packets indicating their current time. Instead, they

listen to all incoming timing packets and set their time to the network time they hear. This assumes that the network time has already previously settled. If no packets are heard during this period, or if times vary widely, then the node enters normal operation with the time it currently has set.

Once in a steady state, the network has a duty cycle of awake and asleep that can be adjusted to control the average power consumed by the network. The timing used in TephraNet is nine minutes asleep followed by one minute of awake time. While the network is awake, each node broadcasts a timing packet approximately every four to six seconds. When a node is asleep, it wakes up approximately every thirty seconds and sends out a timing packet to help nodes that are far off the network time (i.e. awake when they should be asleep) converge to the correct time.

### 3.4.7 Network Configuration and Statistics Gathering

The PARAM module stores TephraNet system settings that can be altered during network operation. These parameters are meant to provide an easy way to change the way the network operates and behaves without having to recompile and reinstall software on each of the nodes. Alterable settings are shown in Table 3.3.

Parameter	Description
PING_SEARCH_COUNT	Number of pings to send when searching for neighbors
PING_LINK_TEST_COUNT	Number of pings sent in a link test
PING_LINK_TEST_DELAY	Time to wait between pings
ARQ_DELAY	Timeout while waiting for an ACK
ARQ_RETRY	Number of time to resend a packet
COST_TTL	Lifetime of a GRAd routing cost table entry
COST_AGE_QUANTUM	How often routing table is purged
GRAD_DISCOVERY_COUNT	How large the initial GRAd discovery cost is
GRAD_ENABLE_RELAY	Enables relaying by this node
MAC_TICKS_PER_BACKOFF	Quantization of MAC backoff timer
AWAKE_TIME	How long to stay awake for in a cycle
SLEEP_TIME	How long to sleep for in a cycle
BASESTATION_ADDR	Address of node that is the current gateway
ARQ_REPORTS	Indicates sensor reports should be ack'd

**Table 3.3 Parameters in a TephraNode**

The STATS module provides a repository for network and node performance statistics. During normal operation, each TephraNode records information about internal statistics (shown in Table 3.4).

Summary information is routinely sent to the gateway node for display and processing.

Statistic	Description
maxTimeDiffThisPeriod	Largest difference between internal time and received time broadcasts this waking cycle
uptime	Uptime of node in OS scheduling ticks
badPackets	Number of corrupted packets seen by radio
goodPackets	Number of valid packets seen by radio
duplicatePackets	Number of duplicate packets seen
gradOriginated	Number of routed packets (not ping or timing) originated by this node
gradFlooded	Number of route discovery floods from this node
gradRelayed	Number of packets relayed for other nodes
arqPktsSent	Number of packets sent with an ack requested
arqPktsRcvd	Number of ACKs received
arqPktsDropped	Number of packets that never got an ack

**Table 3.4 Statistics Gathered**

### 3.5 Summary

This chapter described the goals and design of the TephraNet system. Further design and implementation details are available in the various appendices. The next chapter shows the additional elements added to the TephraNet system that are specific to the Hawaii deployments. The deployments are also reviewed.

## Chapter 4 Implementation and Deployment

Figure 4.1 Joint Project

The TephraNet system design was motivated in large part by the desire to use the system in an actual field deployment for detailed environmental sensing. In collaboration with the Botany department of the University of Hawaii, Manoa campus, the TephraNet system was deployed in Hawaii to study environmental conditions. This section describes the joint project.

### 4.1 Problem Background

*Nene birds, the state bird of Hawaii, are just one of many endangered species living in Hawaii Volcanoes National Park.*

Figure 4.2 Nene Birds

Hawaii Volcanoes National Park on the Big Island of Hawaii contains numerous micro-climate zones. In the space of several miles, the climate zone can change from rainforest to desert. These steep weather gradients are home to many endangered plant and animal species, such as the endangered Nene bird, Hawaii's state bird. One of the goals of the deployment is the measurement of one of these gradients.

Hawaii Volcanoes National Park (dotted region on map) contains numerous microclimate zones, home to many endangered species.

Photo by Michael Hawley

**Figure 4.3 Hawaii Volcanoes National Park**

In one of these microclimate zones, near the crater of Halemaumau, is an area known as the Southwest Rift Zone. The Southwest Rift Zone is thought to be the fastest moving piece of land on the planet. This desert-like zone is home to the *Silene hawaiiensis*, a diminutive endangered plant, usually not taller than half a meter [Bridges01]. Little is known about this plant, or its habitat. Only a few pictures exist of its flowers, and its flowering schedule is unknown. The plant is considered an endangered species.

The *Silene* plant in its native habitat.

Photo by Michael Hawley

**Figure 4.4 *Silene hawaiiensis* in SW Rift Zone**

A detailed picture of the plants' habitat is needed in order to understand their reproductive mechanisms and lifecycle. Knowledge of details about wind speed and patterns can give clues about pollination vectors. For example, if the area is subjected to high winds 24 hours a day, then insects can be ruled out as the pollination mechanism. Data about the amount of rainfall and moisture in the air can help uncover how the plant acquires water. Although the area is thought to be a desert (defined as

less than 15" of rainfall a year), this has yet to be confirmed [Bridges01]. The nearest weather station is only 3.5 miles away, but it is in a rainforest and provides little useful information about the climate these plants exist in.

This particular situation presents an ideal example of environmental measurement where TephraNet is needed. The weather patterns in the Southwest Rift Zone require samples at intervals on the order of a few hundred feet in order to gain a useful understanding of how those patterns act on the *Silene hawaiiensis*. Traditional measurement such as periodic weather stations can not capture this detailed information, and constant human observation is both prohibitively expensive and lacks the granularity required. A dense network of weather stations which will observe the area and continuously report their findings back to botanists studying the area is the ideal solution.

## **4.2 *Deployment Specific System Design***

In order to deploy the TephraNet system as a weather gathering network in the Southwest Rift Zone several additional hardware and packaging components had to be designed.

### **4.2.1 *Sensors***

The sensors added to the TephraNet system transform the generic platform into the weather stations necessary for this research. This section discusses the main characteristics of each sensor. Details on the settings used on the TephraNode board analog inputs and any additional hardware used to attach the sensors can be found in the Hardware Design Appendix A.

#### **4.2.1.1 *Temperature***

The temperature sensor used was a RL1005, manufactured by Thermometrics [Thermometrics01]. It has the ability to measure temperature with 1 degree accuracy from 0 to 150 degrees Celsius. The sensor is of the thermistor class of temperature sensors. The sensor appears as a resistor whose resistance varies inversely with the ambient temperature.

#### 4.2.1.2 Humidity

*The humidity sensors can help determine how the Silene obtains water, and if the SW Rift Zone is a desert.*

*Photo by Michael Hawley*

**Figure 4.5 Humidity Sensor in Rock**

Humidity was measured by a capacitive humidity sensor from Panametrics, the MC-2 [Panametrics01]. The sensor can measure from 0% to 100% relative humidity with approximately 15% accuracy uncalibrated. This sensor appears as a capacitor whose capacitance varies with humidity. Because the basic TephraNet sensor interface only provides the ability to measure analog voltages or resistive values, this sensor required additional hardware to convert the capacitive variance into an analog signal (see Appendix A for details). The humidity level provides an important indicator about the region and can point to the how the Silene obtains water.

#### 4.2.1.3 Wind speed

*Localized wind speed is an important factor in pinpointing pollination vectors.*

*Photo by Michael Hawley*

**Figure 4.6 Wind Sensor showing sail**

Wind speed was measured by using a flex sensor from Abrams Gentile Entertainment [Abrams]. The sensor, originally used in toys, is a force

sensitive resistor that changes value with the degree of deflection. The sensor was modified to measure wind by attaching a small sail to the end of it (see Figure 4.6). The flex sensor is resistive; its resistance changes with the degree of flex. Wind pushes the sail and causes the flex sensor to bend. This novel sensor design was developed by the University of Hawaii and tested in the SW Rift Zone prior to the main deployment.

*Sensors blend into the surface of the fake rocks, and are hardly noticeable.*

Photo by Michael Hawley

**Figure 4.7 Light Sensor Embedded in Fake Rock**

#### **4.2.1.4 Light level**

The light level was measured using a standard photoresistor. This sensor varies resistance proportionally with the amount of light incident on it. This sensor allowed researchers to determine when the area was overcast, and the time of sunrise and sunset.

#### **4.2.2 Power Source**

The lifetime goal for the deployment was six weeks between battery changes. Using a relatively conservative estimate of the nodes power consumption and alkaline battery power, a four D cell configuration was chosen. This configuration was specified to operate clearly within the six week goal.

#### **4.2.3 Gateway Node Antenna**

The gateway node for the network was located in a high observation tower, and was out of the range of the standard antennas selected during the design of the TephraNodes. A directional high gain Yagi antenna was selected to compensate for the distance. Details about the selected antenna can be found in Appendix A, hardware design.

#### 4.2.4 Enclosures

The National Park Service does not permit exposed scientific equipment to be left out in the Southwest Rift Zone. This necessitated the design of camouflaged enclosures to hide the TephraNodes. Mike Lurvey at the University of Hawaii designed fake rocks and tree branches to place the nodes in.

##### 4.2.4.1 Lava Rocks

*The TephraNode sits on top of the batteries for maximum antenna elevation.*

*Figure by Kim Bridges*

**Figure 4.8 Rock Enclosure Drawing**

The majority of the weather stations were enclosed in fake rocks. The study area had many rocks on the order of one foot in diameter. Samples of these rocks were taken from the study area and plaster casts were taken of them. The fake rocks were then constructed out of tinted Bondo and finished by hand-painting (see Figure 4.9). Each of the rocks had sensors mounted into the surface (see Figure 4.7 above). Figure 4.8 shows the placement of the TephraNode within the fake rock.

Photo by Kim Bridges

**Figure 4.9 Rocks at U of Hawaii Awaiting Deployment**

#### 4.2.4.2 Ohia Tree Branches

Figure by Kim Bridges

**Figure 4.10 Ohia Branch Assembly**

The Ohia tree is a native Hawaiian tree that is found near the study area. The fake tree branches were constructed from PVC tubing. The exterior was covered with a printout of bark pattern of the Ohia tree and sprayed with a waterproof coating. A top cap was constructed out of Bondo and color matched. The bottom cap held the batteries and was constructed out of Styrofoam. The bottom cap could be inserted while in the field just prior to deployment. This design held only a temperature and light

sensor. It was strapped into Ohia trees for deployment using plastic cinch straps. Figure 4.10 shows the placement of TephraNode and batteries within the branch. Figure 4.11 shows a placed branch. Although it appears to be quite obvious, from any real distance it is no longer visible unless one is looking for it.

*Although obvious up close, the Ohia branch enclosures are difficult to detect from a distance.*

*Photo by Michael Hawley*

**Figure 4.11 Ohia Branch Enclosure in Tree**

#### **4.2.5 Software**

Several pieces of software were developed for the Hawaii Volcanoes Deployment. On the TephraNode level, a custom application takes sensor readings and sends packets out to a collection point. A gateway application was written that runs on a Linux PC which takes packets from the gateway node and makes them available on a web server. To assist in deployment, a “doctor mode” was added to TephraNode software that allows a computer to attach to a TephraNode and use it to communicate with the TephraNet. Finally, a data visualization suite was developed that displays the data collected from the network for visual analysis.

##### **4.2.5.1 Sensor Application**

Each of the TephraNodes includes software that gathers and reports sensor data. This piece of software averages ten successive readings from each of the sensors in order to filter out noise. The readings are then encapsulated in a packet and routed to the nearest data collection node. The basic packet types described in Section 3.4.4.1 are extended with an APPX\_REPORT type that contains sensor readings. Details about this packet type can be found in the listing for appx.h in Appendix B. The collection interval defaulted to once every ten minutes, although this could be set through the network.

Each node includes software additions to the bootup code. This software runs on startup to run tests and broadcast messages to anyone within radio range about the bootup status. Immediately on boot, the System Manager begins the Synchronization (SYNC) service and broadcasts a message when the node has acquired sync with the network. If sync can not be obtained after some time, the software broadcasts an error message and proceeds. The boot software also listens for neighbors and runs link strength tests to assist in the placement of the node in the network. The results of these tests are broadcast out in informational packets.

#### **4.2.5.2 Doctor Mode**

In order to facilitate deployment, a special doctor mode was designed for the TephraNode software. A node placed into doctor mode communicates with a terminal (such as a Palm Pilot or a laptop) over a serial port, allowing the terminal to monitor information coming from the network and to communicate with nodes in the TephraNet.

<b>Function</b>	<b>Description</b>
Target Node	Selects a node in the network for tests
Collect Neighbors	Collects the single hop neighbors of the target node
Neighbor Strength	Tests link reliability between the target and another node
All Neighbor Strength	Tests link reliability between target and all its one hop neighbors
Test Mode	Causes a node to enter or exit a mode where it never sleeps
Async Ping	Runs a link test to a node the next time it wakes up
Node Existence	Checks if a node (even if asleep) is within radio range
Update Params	Updates the configurable parameters of the target node

**Table 4.1 Doctor Mode Functions**

Doctor mode contained several functions, listed in Table 4.1. Functions such as the async ping and the node existence tests rely on the fact that nodes send a time synchronization packet a few times a minute. During the period of time that the nodes send the synchronization packet, they wake up long enough to process pings. The ping and synchronization

mechanisms are described in more detail in Section 3.4 and in Appendix B. In addition to these functions, the doctor mode prints out messages from the boot sequence (such as a bootup packet, and time sync information) described in the previous section.

*The author uses the doctor mode to log into a deployed rock and debug it.*

Photo by Michael Hawley

**Figure 4.12 Author Logs into a TephraNode**

#### **4.2.5.3 Gateway Software**

A gateway mode was also written for the TephraNodes to allow a node to function as a network gateway. When placed into this mode, the node will print out packets to its serial port. A gateway application, running on a Linux computer, was developed to turn these packets into useful data. The gateway application parses the packet data out of the serial stream and logs it. Another part of the gateway software suite passes over the log file and gathers statistics from it. All of the information is made available through a web server and an HTML based interface. Gateway code can be found in the code listings in Appendix B.

### **4.3 Deployment Plan**

The deployment plan was developed by the author with the University of Hawaii Botany team, led by Dr. Kim Bridges. The deployed system contains three primary components. The base station location contains the network gateway node, which connects the TephraNet network into the Internet. A line of nodes runs from the base station location to the study area, collecting information about the weather gradient and serving as a relay system. The bulk of the nodes in the network are spread out evenly over the study area. The role of each component is presented below with a procedural overview of the deployment.

#### 4.3.1 Base Station

The gateway node was placed in the USGS Volcano Observatory that sits on the rim of the Halemaumau crater (shown in Figure 4.13). The observatory has a high speed Internet connection that allows the data to be reviewed in real time.

*The Halemaumau crater is visible through the observatory window.*

*Photo by Kim Bridges*

**Figure 4.13 Author in Volcano Observatory**

On the top of the observatory is a glass walled "situation" room that served as the headquarters of the deployment operation and also continues to house the base station. This room was used for the final programming of nodes and assembly of Ohia branches and rock packages before being taken into the field. A computer running the gateway software discussed above in Section 4.2.5.3 was located in the observatory. This base station computer allowed remote access to the network, facilitating both data retrieval as well as sending packets into the network.

*Photo by Michael Hawley*

**Figure 4.14 Ohia Branches Awaiting Deployment**

**Figure 4.15 Node Placement Plan**

#### 4.3.2 Node Placement

*Node deployment was planned in two forms- a long string from the observatory and a large field at the study area.*

The Hawaiian Volcano Observatory is over a kilometer from the desired target area in the Southwest Rift Zone. A rough map of the planned deployment is shown in Figure 4.15. The size of the TephraNet was planned to be 80-100 nodes. The nodes are divided into two basic types. The first is a string of nodes running from the observatory to the study area. All of these nodes are housed in Ohia branch enclosures. This string of nodes captures the weather gradient from the observatory, which is often in the clouds, down to the area where the Silene grows, which is believed to be a desert. As the path nears the Silene habitat, the Ohia trees become sparser, and the trail of nodes switches to the rock housings. The plan for this section of the deployment was ensure the network was at least second order to provide redundancy (see Figure 4.16 for an explanation). This string of nodes also acts as the relay for the data coming from the study zone. The approximate spacing between nodes in the trees is 100-150 feet. This long string of nodes allowed the GRAD routing algorithm to be tested in a much larger diameter network than had been done previously.

*Each node should be able to communicate with at least two nodes on either side for increased reliability.*

**Figure 4.16 Overlapping Radio Ranges**

The majority of the nodes are placed in the study area. Since the study area does not have any Ohia trees, all the nodes in this section of the network are in rock enclosures. In this area, the TephraNodes are positioned around 50 ft from each other. This is due primarily to the proximity of the antenna to the ground in the rock setup. RF does not propagate as well when in close proximity to the ground. The spacing plan in this area provides a large amount of redundancy in the network. This network arrangement also provided testing of a dense network configuration with much more opportunity for congestion.

## **4.4 Hawaii Deployment 1**

### **4.4.1 Overview**

The first deployment of the TephraNet system took place in March, 2001. This deployment was planned to be the sole deployment of the system. The intent was to deploy the nodes as described above, and let them run for 6 weeks, collecting data about the network and the environment. Unfortunately, this deployment did not go as planned, although several key lessons were learned in the process. In the week that was spent in Hawaii, the first four days were spent at the University of Hawaii, performing integration between the TephraNet system and the sensors

and software testing. The last three days were spent at the park performing layout planning for the node deployment and testing out nodes.

While in the field, the base station node was set up and the directional antenna was aimed out at the first outdoor node position. Three Ohia branch nodes were deployed into their planned positions, and radio performance was measured with these nodes. After encountering software problems in the nodes that were not correctable in the field most of the remaining time was spent surveying the site and determining the layout of nodes for a future deployment.

#### **4.4.2 Problems Encountered**

##### **4.4.2.1 *Software Reliability***

The most difficult problem encountered during the Hawaii deployment centered on software reliability. On the first field deployment day four nodes were placed into the field. An unknown bug would cause the nodes to crash after forty five minutes to several hours. After eight hours all of the nodes were non-functioning. Due to the time necessary for the error to manifest, the error could not be corrected during the field trial.

Upon return from Hawaii, the node software was analyzed to uncover the source of the instability. The operating system port was found to be at fault. An obscure nested interrupt problem would caused the stack in the operating system to be corrupted when two particular interrupts (such as a packet arrival and a timer) occurred at the same time. The frequency of this occurrence was dependant on the amount of radio traffic. Under heavily loaded conditions, it would usually occur within two hours.

##### **4.4.2.2 *Hardware Problems***

Several problems relating to the hardware also appeared during the deployment. The first was with the base station. As mentioned in the deployment plan, a directional Yagi antenna was used at the base station node in order to provide long range. Even with this antenna, the measured reliability of the link never exceeded 75% (roundtrip packet throughput), which was not reasonable performance. The best guess made in the field was that the antenna was not properly grounded (since

it was in the tower room) or that temperature differentials from inside to outside were adversely affecting the radio. After the deployment exercise completed, the problem was found to be the small AC power supply brick that had been substituted for the battery pack in this node. The power supply generated an extremely noisy power signal, and much of the noise passed through the voltage regulator and negatively affected RF performance.

The RF hardware also acted unreliably in the field, occasionally the radio would get stuck in a mode where it would not output any valid data. Further investigation revealed that human error in the field caused all the radio boards to be programmed repeatedly at a voltage nearly twice the specified programming voltage. Due to this error, the RF transceiver was permanently damaged, and a new run of radio boards were fabricated prior to performing a second deployment.

The power consumption of the hardware platform was also much higher than the expected consumption. Post-field-test examination of the system revealed an undocumented setting in the Atmel microcontroller which accounted for most of the difference between measured and expected power consumption.

#### **4.4.2.3 *Misc. Problems***

Even in the medium volume of one hundred nodes, many little design issues become huge headaches. One such issue relates to the stacking of the boards. The radio and processor board are stacked and attached using nylon spacers and screws (see Figure 3.1). The design precluded inserting the programming header for the main processor when the boards are stacked. This added a prohibitive amount of assembly overhead in the field and made field corrections of software mistakes difficult. Requiring the boards to be screwed together also added hours of assembly overhead.

A final problem encountered was with the connectors between the battery packs and the TephraNode hardware. A mismatch in parts went undetected until assembly in Hawaii. The part problem required the power supply wires to be soldered directly to the nodes instead of using a connector.

#### 4.4.3 What Went Right

Despite all of the problems encountered on the first deployment, several positive things came out of the experience. Perhaps the most valuable was the ability to verify that the pieces designed with each team interoperated. The sensors successfully attached to the TephraNodes and sensor readings were taken. The TephraNode hardware fit successfully within the rock and Ohia branch housings. The time in the field was also an excellent opportunity for the MIT and University of Hawaii teams to meet in person and communicate.

### 4.5 Hawaii Deployment 2

#### 4.5.1 Overview

After the software stability issues were corrected and new radio hardware was manufactured, a second deployment was performed in June of 2001. This second deployment, although still not entirely successful, provided great insight into the performance of the GRAd routing algorithm and the usability of the TephraNet platform for field work.

*The string of nodes headed toward the SW Rift Zone were deployed successfully.*

Figure 4.17 Deployed Node Positions

During this deployment, the entire line of nodes running out to the study site was deployed (see Figure 4.17). In addition, a *Silene hawaiiensis* population was discovered near the Volcano Observatory, off of the planned deployment track. The team decided to take advantage of this monitoring opportunity, and deployed the first TephraNodes in rock enclosures in this area. Around three days was spent in the park deploying both the nodes going to the study site, and those around the Observatory.

#### **4.5.2 Problems Encountered**

##### **4.5.2.1 Power Supply Noise**

*Power supply noise negatively impacted radio performance.*

As mentioned in the description of the first deployment, the link from the base station node out to the first outdoor node functioned poorly. Experimentation during the first day of the second deployment revealed that the source of the poor performance was noise generated from the power supply. It was replaced by a clean power supply. In addition to this problem, a problem with the power regulator on each node was also discovered after several nodes were deployed on the first day. The nodes demonstrated packet reliability on the order of 50% even over moderate distances. Experimentation uncovered noise in the power supply as the main problem. Work done in the laboratory had often bypassed the on-board power supply in favor of an external one that could source the current necessary for all the programmers, and so the problem was not detected prior to field work.

This problem was partially overcome by implementing a simple FEC (forward error correcting) code in the radio. An FEC achieves higher reliability at the expense of bandwidth by sending redundant information. The code used was a simple block code where each byte of data is sent three times, and the receiver uses the three bits received to vote on the value (i.e. if two zeros and a one arrive for a particular bit, the receiver decides that the bit is a zero). This technique improved the bit error rates to over 90% in the 100 ft distance range.

##### **4.5.3 Ease of Deployment**

One unanticipated problem faced during this deployment was the ease of deployment. The actual placement of the nodes took much longer than

expected, and the correction of any errors once a node was placed was difficult. Most nodes placed were of the Ohia branch type, which often involved climbing a tree with the branch and securing it with plastic zip-ties. Once a tree was identified as the node location, the node was powered up and the author stood by with a doctor mode system as described in Section 4.2.5.2 to watch the node boot. Obtaining link tests to neighbors to assure a reliable positioning consumed the majority of deployment time. The branch was often high in the tree, and someone had to hold the branch in place while the tests ran. Since deployed nodes were usually in their sleep cycle, and woke only every thirty seconds or so, running several link tests took minutes. Adjusting the branch slightly and running more tests was extremely time consuming. As a result of the difficulty of the deployment, nodes were often placed in sub-optimal locations and not enough time was available to deploy all nodes.

*Mike Lurvey of the University of Hawaii places an Ohia branch node into a tree.*

*Photo by Michael Hawley*

**Figure 4.18 Placing Node in Ohia Tree**

Another major issue surrounding the ease of deployment was the difficulty making any changes to the deployed system. Although a mechanism was present to change certain parameters of the deployed system, the main body of the software could not be modified without taking the nodes out of the trees, disassembling them, and reprogramming them by physically attaching to them. For an experimental system intended to be a testbed, this is not acceptable.

#### **4.5.4 Synchronization and Routing Algorithm Problems**

The TephraNet system suffered from several synchronization and routing problems after deployment. Once deployed, the system appeared to have

major problems settling in on a common time. The time at each node determines when it is awake and asleep. If all the nodes in the network do not wake up at the same time, a packet can not be relayed through the network. The time synchronization thus prevented packets from being routed successfully through the network. A complete analysis of the synchronization problem is provided below in Chapter 5.

The GRAd routing algorithm itself also suffered from performance issues. Data indicated that very few packets from further than 3 or 4 hops away was successfully reaching the base node, despite the fact that over 20 hops worth of nodes were deployed. This low reliability was seen even with end-to-end per-packet acknowledgements in place. A detailed analysis of the data collected relating to the routing problem is presented below in the analysis section.

Overall, these algorithmic problems prevented the deployment from being fully successful.

## **4.6** *Summary*

This section illustrated what was required to use the basic TephraNet platform in an environmental sensing application. The Hawaii Volcanoes specific implementation was detailed and a plan for deployment was presented. The two deployment activities in Hawaii were reviewed. The next section presents the lessons learned on the deployment and draws conclusions about how the project met its goals.

## Chapter 5 Results and Conclusions

This chapter analyzes the data collected about network operation from the two field deployments. An evaluation of how well the TephraNet design met its stated design goals is also presented. Finally, future areas of work and the contributions of TephraNet are discussed.

### 5.1 Analysis

This section presents an analysis of the major problems found during the field tests. An analysis of how well the TephraNet system measured up to its stated goals is also presented.

#### 5.1.1 Ease of Use- The End User Perspective

*Ease of use from the end user's perspective is an important design consideration that was not stressed enough.*

The field tests revealed the importance of ease of use issues if a network platform is to become a routinely used environmental research tool. As mentioned in chapter two, most of the research in self-organizing networks has focused on routing algorithms. These self-configuring algorithms alleviate much of the pain of setting up a complex multi-hop wireless network. However, the network routing is only a small piece of the entire usage experience.

The design of the TephraNet system attempted to take ease of use into account. The system included tools for nodes that were intended to ease the deployment of a network, such as the doctor mode, which provided a deployment team with an easy way to view what was occurring in the network. However, a researcher faced with the reality of a steady strong wind twenty feet above the ground in a treetop, while holding too many things, quickly finds these tools clumsy and overly complicated. The delays in determining if a node was placed well — on the order of several minutes — became unacceptably long once in the field.

*Holding nodes in position while link tests are obtained proved to be highly taxing.*

Photo by Michael Hawley

**Figure 5.1 Difficulty with Placement**

Any design that is to succeed in a field such as environmental sensing must make deployment totally painless. An absolute minimum of knowledge should be required of the deployment team, or they will reject the new tool. The user should ideally be able to simply turn on a node, and view a green light if it is in a good position to join the network, or a red light if it is in a bad position. Multiple modes should be avoided at all costs unless switching between them is totally autonomous. Future work should examine the utilization of the system from the perspective of the targeted end user, and ensure that the system is as easy to use as is required.

### **5.1.2 Sensor Network Demonstration**

As discussed in Chapter 4, the deployment of the system was not smooth. The problems encountered with the synchronization and routing algorithms (discussed below) prevented any useful amount of data from being gathered. The current deployment failed to collect information about the *Silene* environment, but did make a large step towards doing so. In order for the system to work as a sensor network demonstration, the synchronization and routing algorithms need to be fixed. Potential fixes for these algorithms are discussed in Section 5.1.5 and 5.1.6.

Feedback from the researchers at the University of Hawaii clearly indicates that this tool is both valuable and necessary to further the study of the environment. The current system already presented many of the

characteristics required of such an environmental tool, and with further refinement, could be used widely for field research.

### **5.1.3 Network Algorithm Testbed**

The other main goal of this thesis was to present a viable hardware platform on which to test self-organizing wireless network algorithms. The TephraNet platform successfully obtained this goal, acting as a platform that uncovered several interesting results about the GRAd routing algorithm that had not been obtained through analysis in simulation. Further refinements to the hardware could result in a system even more manufacturable and lower cost than the current design, giving researchers a platform that can be scaled to large numbers. The scalability and operation of network routing algorithms outside of simulation is important to test, and the TephraNet platform goes a long way toward providing a common platform on which to do those tests.

### **5.1.4 System Goal Analysis**

The TephraNet system was designed with several design goals in mind, presented in Section 3.2. Each of these goals was met with varying degrees of success.

#### **5.1.4.1 Manufacturability**

The TephraNet system proved to have several manufacturability issues that should be corrected in future revisions. One is the presence of the uBGA package Intel flash chip. This package requires feature sizes on the board below standard sizes (5 mils) and special handling during assembly. This increases the cost of manufacturing significantly. The other problem was the calibration required at the RF level. The radios require tuning and measurement of several parameters, which should either be eliminated or automated since it is prohibitively time consuming.

#### **5.1.4.2 Low Power**

TephraNet met its low power goal well. The system consumes a minimum amount of power (both running and asleep) for the feature set it incorporates, due to careful component selection and design. To further optimize power consumption, a more efficient RF design can be

considered and more rigorous power management at the software level can be developed.

#### **5.1.4.3 *Ease of Development and Software Flexibility***

The ease of software development goal was met adequately. The choice of a standard operating system is a major factor in easing development. The interfaces between the various software modules in TephraNet can be improved, so that new software can be more readily integrated. The ease with which the system is programmed also needs improvement. Currently the system requires disassembly for programming. Ideally, the system would support in-network programming and a simpler out-of-network programming system than is currently in place.

#### **5.1.4.4 *Autonomous***

Although the system was designed with this goal in mind, and tools were put in place to meet this goal, the system did not perform as well as required. As mentioned above, the system required too much user intervention to be truly easy to use. The failure of the synchronization system also significantly lowers the autonomy of the system.

#### **5.1.5 Routing Algorithm Performance Analysis**

Analysis of the TephraNet's network performance revealed two primary points of algorithmic failure.

The first error encountered was related to the non-ideal link reliability characteristics. During network operation, not many packets originating from nodes beyond three or four hops away from the base station node ever reached the base station. The GRAd algorithm relies on end-to-end acknowledgements of packets to verify receipt. If a node does not receive an acknowledgement to a sent packet, it resends up to a maximum number of retries (six times in the Hawaii deployment). Figure 5.4 below shows an average scenario of link reliability observed in the field. A basic, first order calculation of the probability of a packet reaching its destination in the GRAd network is simply  $p^n$ , where  $p$  is the probability of successfully going a single hop, and  $n$  is the number of hops. As the graph in Figure 5.2 shows, this probability quickly approaches an unacceptably low number. Even accounting for retries and second order effects (lower, but

non-zero probabilities of going through a 2<sup>nd</sup> degree neighbor directly), the probabilities are still well below reasonable levels.

*Probability of a successful multi-hop transmission without per-hop acknowledgements rapidly decreases with number of hops.*

**Figure 5.2 Probability of Multi-hop Success**

In a network of unreliable links, a pure broadcast end-to-end approach, such as that advocated by the original GRAd algorithm is not ideal. Other routing algorithms, such as AODV and DSR route data through specific nodes. As shown in [Wheeler00], this selection of specific neighbors for transmission often requires additional routing overhead and algorithmic complexity. One possible solution that would not require much additional overhead is the use of a “passive per-hop acknowledgement.” With this system, a node which relays a packet waits to see if it hears another node relay the same packet at a lower advertised cost. If none is heard within a timeout period, the packet can be resent. If this is used through the whole chain of nodes, it has the potential to significantly increase the reliability of the network.

*Abnormal RF propagation prevented normal network operation due to an algorithmic deficiency.*

**Figure 5.3 Long Distance RF Communications**

The second observed behavior within the network was the occasional receipt of packets from a cluster of nodes far from the base station node (see Figure 5.3). This node cluster was over a kilometer from the Volcano Observatory tower, although one of the nodes could occasionally get a packet through the link. Several of the surrounding nodes occasionally reported data back to the Observatory using this highly unreliable link. A related occurrence was several nodes near the base station only sending packets through short-hop count, but highly unreliable links, even though a longer, more reliable path existed (see Figure 5.4).

**Figure 5.4 Unreliable Link Selection**

Both of these occurrences are related to the same underlying problem. GRAd, and most other ad-hoc networking algorithms use a hop count as the sole metric for determining the distance of a route through a network. In the case of the Hawaii TephraNet deployment, the unreliable links caused the network to resend packets many times. Probabilistically, every once in a while a packet will traverse the shorter, less reliable link. When this occurs, an artificially low distance is recorded by the algorithm. When the nodes attempt to communicate again, they will specify the low hop-count path as the distance, and the packets will almost certainly fail to arrive at the destination.

This problem affects not only the GRAd algorithm, but the entire class of algorithms that use only hop count as the metric for route selection. Several possibilities exist for correcting this problem. One is to weight the hop count by some factor that takes into account link reliability. This requires that some method of measuring link reliability be found. Sending explicit ping packets could work, but would add a large amount of overhead to the network operation. One possibility would be to use the RSSI (received signal strength indicator) to judge the approximate RF quality of the link. Most radio systems, including the TephraNet system, have this output available.

### 5.1.6 Synchronization System Review

The synchronization system (described in Section 3.4.6) was responsible for keeping network time consistent through the network. The time in turn controlled sleeping and waking cycles in the system for power management purposes. Analysis of the exact causes of the failure of the synchronization system is difficult because detailed timing data was not sent back to the base station node through the network *and* when the synchronization system failed, the whole network often failed. Observation of the system revealed several problems that were corrected in the field, and point to a further problem that was not corrected.

Early revisions implemented the algorithm exactly as proposed by Poor in [Poor01]. This quickly proved to require a large settling time and had a hard time recovering from the constant addition of new nodes to the network (each of them injected a new time that had to be averaged in). A startup period was added that listened to timing packets and simply set the internal time to the time heard instead of averaging. This alleviated most of the settling time issues.

The next problem encountered was that the sleep cycle of a node has nine times as much sleeping time as waking time. If a node somehow is off of the network time enough that its waking time is while the other nodes are asleep, the node never hears the correct time, and cannot recover. This was fixed by causing each node to wake up briefly several times during its sleeping time to broadcast a timing packet.

Even with the above corrections, the network appeared to get into situations where synchronization was lost. Analysis of the data reveals that even with the broadcast of timing packets while asleep, the system did not recover once a node was no longer awake when other nodes were. Since the degree of connectivity in the network was poor, the settling time of the network was large—each node only averaged time with a neighbor or two on each side. Once timing is off, a situation can arise where a node is directly between its two neighbors in time, but far enough away in timing that it is never awake at the same time as either of its neighbors. When this happens the node in the center does not actually adjust its time at all,

and the nodes on the side will take many sleep cycles to adjust their time, and may also fail to adjust it meaningfully.

These stability problems with the algorithm indicate it is not appropriate for use in a network like TephraNet. Previous simulation of the algorithm failed to simulate static networks and networks that alternate between a sleeping and waking period.

## **5.2 *Future work***

The work started in TephraNet made a large step forward in establishing self-organizing wireless networks as a valuable research tool for environmental research, and toward establishing a common platform on which to test these network algorithms. However, much additional work remains to improve on what has been started.

### **5.2.1 Redesign of Hardware Platform**

The hardware platform should be redesigned in order to increase its manufacturability. The current platform contains certain components, such as the uBGA packaged flash chip that significantly increase the complexity and cost of the system. The 2 board design should also be revisited, either finding a new stacking method, or condensing onto a single board. This will ease the programmability and handling of the platform in the field.

### **5.2.2 Long Term Deployment and Other Deployments**

In order to fully prove the usefulness of this technology in the field of environmental research, a long term deployment should be done. Additional information about the performance of the routing algorithms and system could potentially be uncovered if tested for a longer time period. The TephraNet system should also be deployed into other areas besides the Hawaii Volcanoes site to determine its general usefulness.

### **5.2.3 Use as a Test Platform**

In order to further evaluate the usefulness of the TephraNet platform as a test bed for network routing algorithms, more of these algorithms should be implemented on the system. Continued detailed analysis of the differences between results seen in simulation and on the platform should

be conducted to uncover potential problems in the design of the platform or the simulator.

#### **5.2.4 Software Toolkit Refinements**

The software portion of the TephraNet system can benefit from several additional features. In order for the system to be a viable test platform, it should be easy to gather data about the operating network and to make changes to the running code. This points to the need for software on the platform to be interchangeable with a minimum amount of effort. Ideally, this could be done directly through the network and also through a back-channel, such as a wired network attached to each node.

#### **5.2.5 Refinement of Software Algorithms**

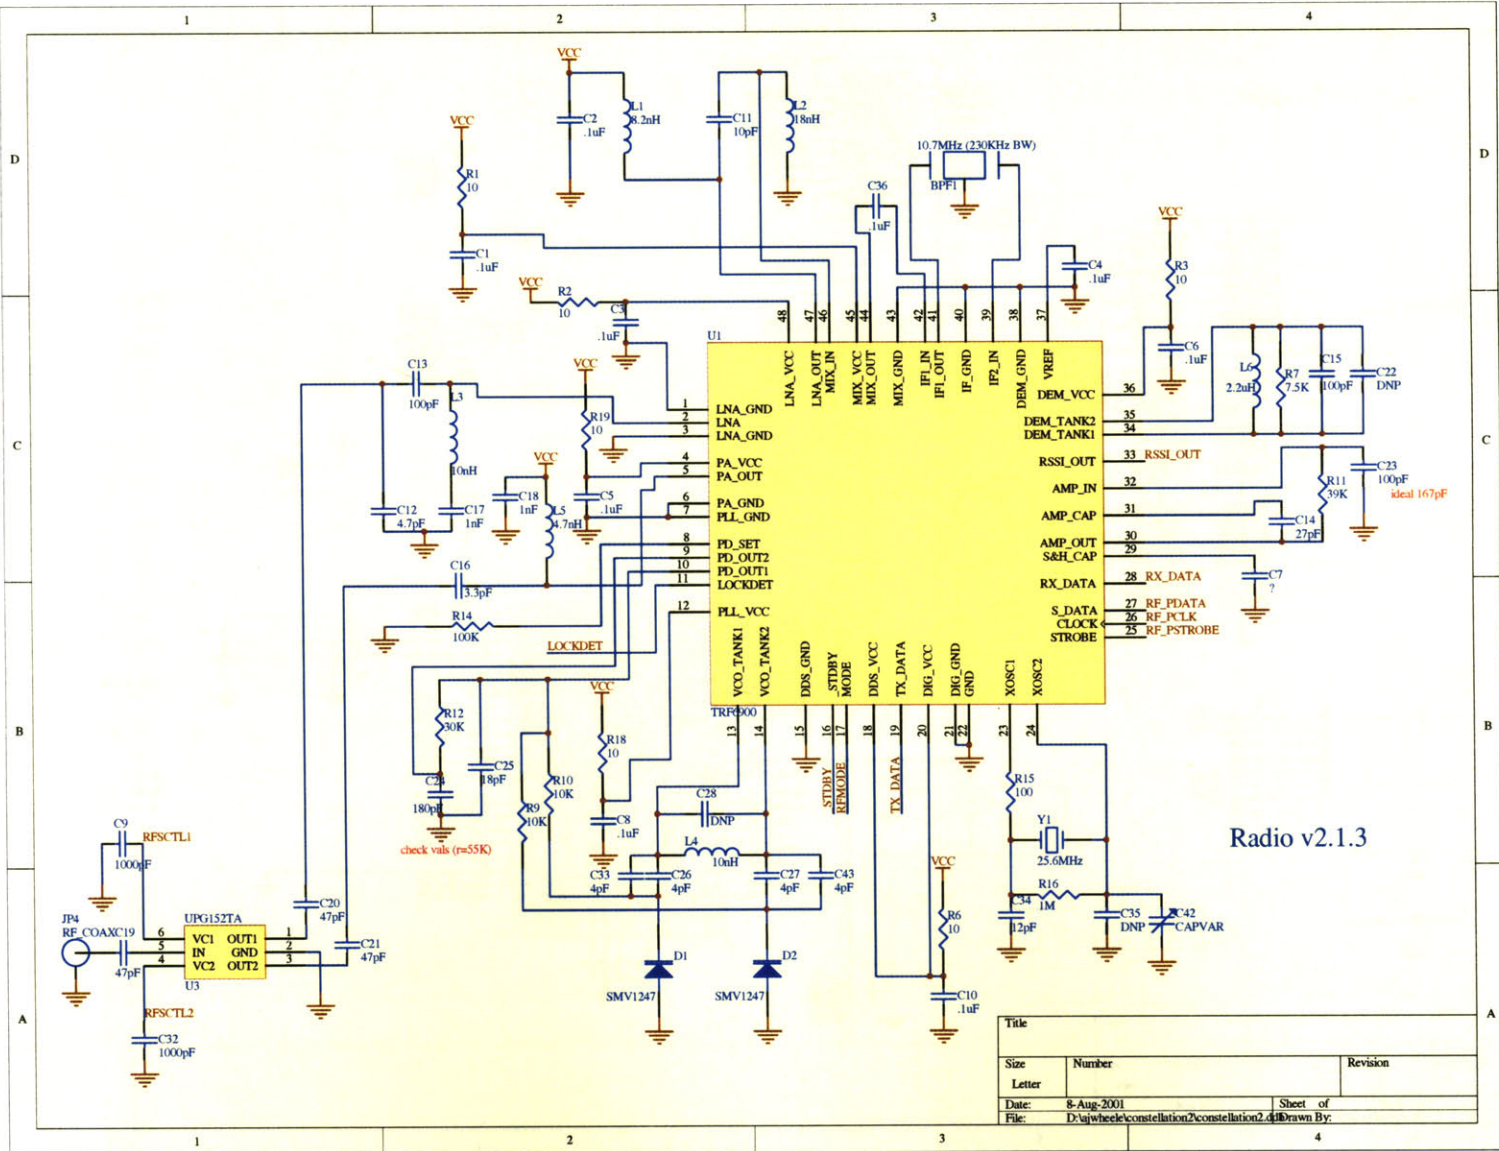

The synchronization and routing algorithms play key roles in the operation of TephraNet for environmental sensing. Since these two components did not function correctly, they should be reworked. The suggestions posed in the analysis (Section 5.1.5) should be tested out as possible solutions to the algorithmic problems.

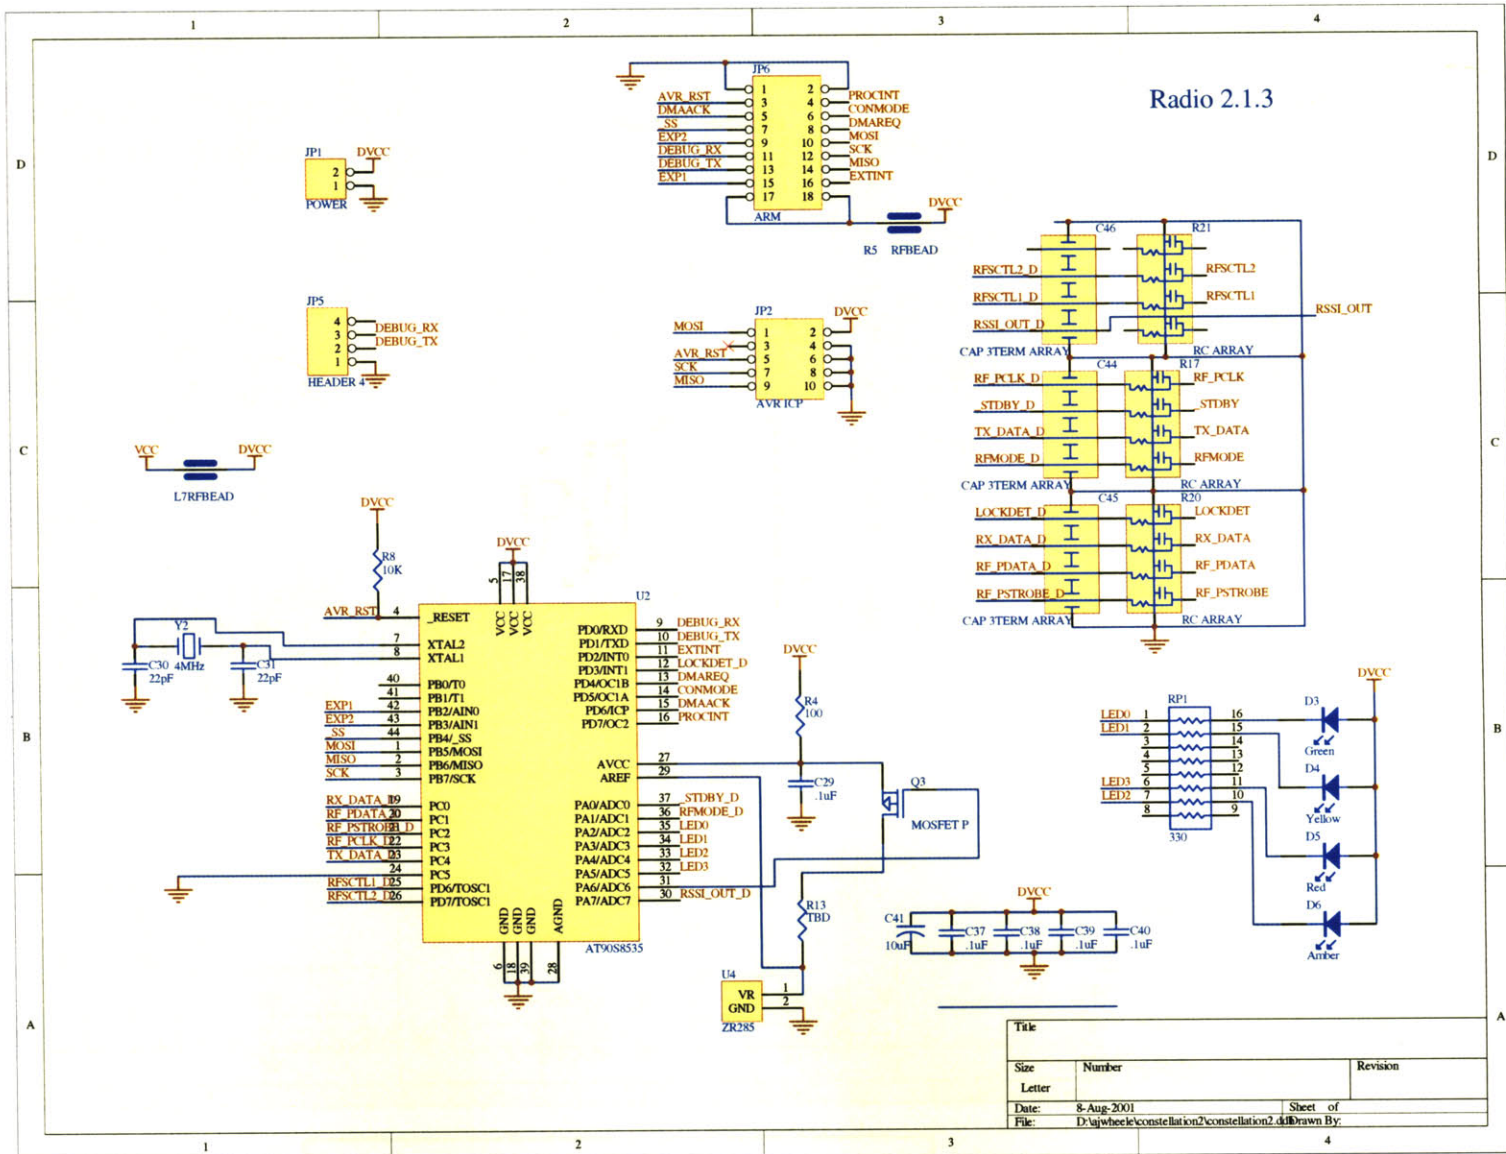

### **5.3 *Contributions and Conclusions***

The TephraNet system made several contributions to the areas of self-organizing network research and to environmental sensing tools. The TephraNet system introduced self-organizing networks as a tool for environmental research and made a significant step towards demonstrating a working system for that application. The system also presents a first revision of a common hardware and software toolkit for both environmental sensing and the testing of ad-hoc network routing algorithms. Significant problems with the current formulation of both GRAd and other hop-count based algorithms were also uncovered. Future work with the TephraNet platform should help advance both the fields of environmental sensing and ad-hoc wireless networking.

# Bill of Materials for Processor

## Appendix B: Source Code Listings

This appendix contains a partial listing of the source code for the TephraNet system. The code contained here implements most of the important functionality in the system. The following code is not listed here: code running on radio baseband controller, bootloader for node, testing and programming code for node, code running on base station computers, and operating system port for node. Also not listed is “helper code” implementation- i.e. code that does not provide major functionality. For those files, only the header is listed. Readers interested in code not listed here, or obtaining the following code in electronic form should contact the author. Code is listed header file first, followed by c file. Tephra is listed first, which is the boot code. Subsequent files are in alphabetical order. See the software description in Chapter 3 for an explanation of the various modules.

#include "node_id.h"
#include "types.h"
#include "pseg.h"

// Ping service:
//
// In response to a PSEG_TYPE_NEIGHBOR_REQUEST message, ping will
// find all neighboring nodes and send a PSEG_TYPE_NEIGHBOR_REPORT
// back to the requestor.
//
// In response to a PSEG_TYPE_LINK_REQUEST message, ping will enter
// into a link test loop with a specific neighbor and send the results
// back to the requestor in a PSEG_TYPE_LINK_REPORT message.
//
// Internally, ping will generate and receive PSEG_TYPE_PING and
// PSEG_TYPE_PONG messages as part of the discovery and link test
// procedures.

// Some things that the ping service does:
//
// find all (one hop) neighbors
// gather channel statistics to a specific (one hop) neighbor
// determine connectivity to a remote neighbor
```

```
#define PING_MAX_NEIGHBORS 10
